Description

encode creates a new variable named *newvar* based on the string variable *varname*, creating, adding to, or just using (as necessary) the value label *newvar* or, if specified, *name*. Do not use encode if *varname* contains numbers that merely happen to be stored as strings; instead, use generate *newvar* = real(*varname*) or destring; see [U] **24.2 Categorical string variables**, [FN] **String functions**, and [D] **destring**.

decode creates a new string variable named *newvar* based on the "encoded" numeric variable *varname* and its value label.

Quick start

Generate numeric newv1 from string v1, using the values of v1 to create a value label that is applied to newv1

```
encode v1, generate(newv1)
```

As above, but name the value label mylabel1

```
encode v1, generate(newv1) label(mylabel1)
```

As above, but refuse to encode v1 if values exist in v1 that are not present in preexisting value label mylabel1

```
encode v1, generate(newv1) label(mylabel1) noextend
```

Convert numeric v2 to string newv2 using the value label applied to v2 to generate values of newv2 decode v2, generate(newv2)

Syntax

String variable to numeric variable

```
encode varname [if] [in], generate(newvar) [label(name) noextend]
```

Numeric variable to string variable

```
\underline{\mathtt{dec}}\mathtt{ode}\ \mathit{varname}\ \left[\mathit{if}\ \right]\ \left[\mathit{in}\ \right]\ ,\ \underline{\mathtt{generate}}(\mathit{newvar})\ \left[\,\underline{\mathtt{maxl}}\mathtt{ength}(\#)\ \right]
```

Options for encode

generate(newvar) is required and specifies the name of the variable to be created.

label(name) specifies the name of the value label to be created or used and added to if the named value label already exists. If label() is not specified, encode uses the same name for the label as it does for the new variable.

noextend specifies that varname not be encoded if there are values contained in varname that are not present in label(name). By default, any values not present in label(name) will be added to that label.

Options for decode

generate(newvar) is required and specifies the name of the variable to be created.

maxlength(#) specifies how many bytes of the value label to retain; # must be between 1 and 32,000. The default is maxlength(32000).

Remarks and examples

stata.com

Remarks are presented under the following headings:

encode decode Video example

encode

encode is most useful in making string variables accessible to Stata's statistical routines, most of which can work only with numeric variables. encode is also useful in reducing the size of a dataset. If you are not familiar with value labels, read [U] 12.6.3 Value labels.

The maximum number of associations within each value label is 65,536. Each association in a value label maps a string of up to 32,000 bytes to a number. For plain ASCII text, the number of bytes is equal to the number of characters. If your string has other Unicode characters, the number of bytes is greater than the number of characters. See [U] 12.4.2 Handling Unicode strings. If your variable contains string values longer than 32,000 bytes, then only the first 32,000 bytes are retained and assigned as a value label to a number.

Example 1

We have a dataset on high blood pressure, and among the variables is sex, a string variable containing either "male" or "female". We wish to run a regression of high blood pressure on race, sex, and age group. We type regress hbp race sex age_grp and get the message "no observations".

- . use https://www.stata-press.com/data/r17/hbp2
- . regress hbp sex race age_grp

no observations r(2000);

Stata's statistical procedures cannot directly deal with string variables; as far as they are concerned, all observations on sex are missing. encode provides the solution:

- . encode sex, gen(gender)
- . regress hbp gender race age_grp

Source	SS	df	MS	Number of ob	-	1,121
Model Residual	2.01013476 49.3886164	3 1,117	.67004492 .044215413	R-squared	= = =	15.15 0.0000 0.0391 0.0365
Total	51.3987511	1,120	.045891742	- Adj R-square Root MSE	u – =	.21027
	T					
hbp	Coefficient	Std. err.	t	P> t [95%	conf.	interval]

encode looks at a string variable and makes an internal table of all the values it takes on, here "male" and "female". It then alphabetizes that list and assigns numeric codes to each entry. Thus 1 becomes "female" and 2 becomes "male". It creates a new int variable (gender) and substitutes a 1 where sex is "female", a 2 where sex is "male", and a missing (.) where sex is null (""). It creates a value label (also named gender) that records the mapping $1 \leftrightarrow$ female and $2 \leftrightarrow$ male. Finally, encode labels the values of the new variable with the value label.

1

Example 2

It is difficult to distinguish the result of encode from the original string variable. For instance, in our last two examples, we typed encode sex, gen(gender). Let's compare the two variables:

. list sex gender in 1/4

sex	gender
female	female
male male	male male
	female male

They look almost identical, although you should notice the missing value for gender in the second observation.

The difference does show, however, if we tell list to ignore the value labels and show how the data really appear:

. list sex gender in 1/4, nolabel

sex	gender
female	1
male male	2 2
	female male

We could also ask to see the underlying value label:

. label list gender gender: 1 female 2 male

gender really is a numeric variable, but because all Stata commands understand value labels, the variable displays as "male" and "female", just as the underlying string variable sex would.

4

Example 3

We can drastically reduce the size of our dataset by encoding strings and then discarding the underlying string variable. We have a string variable, sex, that records each person's sex as "male" and "female". Because female has six characters, the variable is stored as a str6.

We can encode the sex variable and use compress to store the variable as a byte, which takes only 1 byte. Because our dataset contains 1,130 people, the string variable takes 6,780 bytes, but the encoded variable will take only 1,130 bytes.

- . use https://www.stata-press.com/data/r17/hbp2, clear

Note: Dataset has changed since last saved.

1,130

The size of our dataset has fallen from 24,860 bytes to 19,210 bytes.

□ Technical note

In the examples above, the value label did not exist before encode created it, because that is not required. If the value label does exist, encode uses your encoding as far as it can and adds new mappings for anything not found in your value label. For instance, if you wanted "female" to be encoded as 0 rather than 1 (possibly for use in linear regression), you could type

- . label define gender 0 "female"
- . encode sex, gen(gender)

You can also specify the name of the value label. If you do not, the value label is assumed to have the same name as the newly created variable. For instance,

- . label define sex1bl 0 "female"
- . encode sex, gen(gender) label(sexlbl)

decode

decode is used to convert numeric variables with associated value labels into true string variables.

Example 4

We have a numeric variable named female that records the values 0 and 1. female is associated with a value label named sex1b1 that says that 0 means male and 1 means female:

- . use https://www.stata-press.com/data/r17/hbp3, clear
- . describe female

Variable name	Storage type	Display format	Value label	Variable label
female	byte	%8.0g	sexlbl	Female
. label list sexlbl:	t sexlbl			
() Male			
:	l Female			

We see that female is stored as a byte. It is a numeric variable. Nevertheless, it has an associated value label describing what the numeric codes mean, so if we tabulate the variable, for instance, it appears to contain the strings "male" and "female":

. tabulate female

Female	Freq.	Percent	Cum.
Male Female	695 433	61.61 38.39	61.61 100.00
Total	1,128	100.00	

We can create a real string variable from this numerically encoded variable by using decode:

- . decode female, gen(sex)
- . describe sex

Variable name	Storage type		Value label	Variable label	
sex	str6	%9s		Female	

We have a new variable called sex. It is a string, and Stata automatically created the shortest possible string. The word "female" has six characters, so our new variable is a str6. female and sex appear indistinguishable:

. list female sex in 1/4

	female	sex
1. 2.	Female	Female
3. 4.	Male Male	Male Male
	naic	naic

But when we add nolabel, the difference is apparent:

. list female sex in 1/4, nolabel

	female	sex
1. 2.	1	Female
3.	0	Male
4.	0	Male

Example 5

decode is most useful in instances when we wish to match-merge two datasets on a variable that has been encoded inconsistently.

For instance, we have two datasets on individual states in which one of the variables (state) takes on values such as "CA" and "NY". The state variable was originally a string, but along the way the variable was encoded into an integer with a corresponding value label in one or both datasets.

We wish to merge these two datasets, but either 1) one of the datasets has a string variable for state and the other an encoded variable or 2) although both are numeric, we are not certain that the codings are consistent. Perhaps "CA" has been coded 5 in one dataset and 6 in another.

Because decode will take an encoded variable and turn it back into a string, decode provides the solution:

use first (load the first dataset) (make a string state variable) decode state, gen(st) (discard the encoded variable) drop state (sort on string) sort st (save the dataset) save first, replace (load the second dataset) use second (make a string variable) decode state, gen(st) drop state (discard the encoded variable) sort st (sort on string) (merge the data) merge 1:1 st using first
